The photoinhibition of photosystem I (PSI) is lethal to oxygenic phototrophs. Nevertheless, it is unclear how photodamage occurs or how oxygenic phototrophs prevent it. Here, we provide evidence that keeping P700 (the reaction center chlorophyll in PSI) oxidized protects PSI. Previous studies have suggested that PSI photoinhibition does not occur in the two model cyanobacteria, *Synechocystis* sp. PCC 6803 and *Synechococcus elongatus* PCC 7942, when photosynthetic CO2 fixation was suppressed under low CO2 partial pressure even in mutants deficient in flavodoxin protein (FLV), which mediates alternative electron flow. The lack of FLV in *Synechococcus* sp. PCC 7002 (S. 7002), however, is linked directly to reduced growth and PSI photodamage under CO2-limiting conditions. Unlike *Synechocystis* sp. PCC 6803 and *S. elongatus* PCC 7942, S. 7002 reduced P700 during CO2-limited illumination in the absence of FLV, resulting in decreases in both PSI and photosynthetic activities. Even at normal air CO2 concentration, the growth of S. 7002 mutant was retarded relative to that of the wild type. Therefore, P700 oxidation is essential for protecting PSI against photoinhibition. Here, we present various strategies to alleviate PSI photoinhibition in cyanobacteria.

Low CO2 fixation efficiency in the Calvin-Benson cycle prevents the utilization of NADPH and ATP in photosynthesis and causes these molecules to accumulate, resulting in oxidative photosynthetic cell damage. High light, low temperature, and CO2 limitation increase NADPH and ATP levels beyond the Calvin-Benson cycle requirements. Electrons and H+ accumulate in the photosynthetic electron transport (PET) system. Excess electrons in the PET system trigger oxidative damage to PSI by forming reactive oxygen species (ROS), including the superoxide anion radical (O2−) and singlet oxygen (1O2), within PSI and degrading the P700 reaction center chlorophyll (P700; Sonoike, 1996; Sejima et al., 2014; Zivcak et al., 2015a, 2015b; Takagi et al., 2016). PSI repair has been reported to be a very slow process (Kudoh and Sonoike, 2002), and a recent study showed that it took more than 12 d for damaged PSI in wheat (*Triticum aestivum*) leaves to recover completely (Zivcak et al., 2015b). PSI photoinhibition, therefore, is very detrimental to oxygenic phototroph growth. Nevertheless, PSI photoinhibition is alleviated by keeping P700 oxidized (Sejima et al., 2014).

In the PET system of oxygenic phototrophs, P700 oxidation is a physiological response to environmental variations. In *C3* plants, low CO2 and/or high light intensity induce P700 oxidation in vivo (Klughammer and Schreiber, 1994; Laisk and Oja, 1994; Miyake et al., 2004, 2005). Several molecular mechanisms are proposed for P700 oxidation wherein the PSI acceptor does not limit the PET reaction. First, H+ accumulation on the luminal side of thylakoid membranes lowers reduced plastoquinone (plastoquinol) oxidation rates in the cytochrome (Cyt) b6/f complex (Kramer et al., 1999). Second, plastidial terminal oxidase and cyanobacterial respiratory terminal oxidases on the thylakoid membranes suppress PSI electron influx by accepting upstream PSI electrons in the PET system. Oxygen is the final electron acceptor (Beardall et al., 2003; Trouillard et al., 2012; Lea-Smith et al., 2013). Finally, plastoquinol accumulation inhibits the Q-cycle turnover in the Cyt b6/f complex, which suppresses electron flow from the Cyt b6/f complex to P700. This reaction is called the reduction-induced suppression of electron flow (RISE; Shaku et al., 2016). Overall, these molecular mechanisms contribute to P700 oxidation, thereby preventing PSI photoinhibition and enabling oxygenic phototrophs to thrive. The proton gradient regulation5 (pgr5) mutant of Arabidopsis (*Arabidopsis thaliana*) cannot

keep P700 oxidized and shows PSI photoinhibition under high-light and fluctuating light conditions (Munekage et al., 2002; Suorsa et al., 2012), which shows the importance of the oxidation of P700 for the protection of PSI in plants.

Unlike green plants, P700 oxidation mechanisms in cyanobacteria are unclear. It is known that flavodiiron protein (FLV) could contribute to P700 oxidation. Four FLV isoforms (FLV1−FLV4) have been identified in the model cyanobacterium Synechocystis sp. PCC 6803 (S. 6803; Helman et al., 2003). FLV1 and FLV3 (FLV1/3) function as a heterodimer and catalyze the reduction of oxygen to water on the acceptor side of PSI using NAD(P)H as electron donors (Vicente et al., 2002; Helman et al., 2003; Allahverdiyeva et al., 2013). Unlike FLV1/3, FLV2/4 is induced only under low CO2 (Zhang et al., 2009) and mediates an oxygen-dependent alternative electron flow (AEF; Shimakawa et al., 2015). In S. 6803, FLV-dependent electron fluxes are coupled to photosynthesis and should alleviate electron overaccumulation in PSI (Helman et al., 2003, 2005; Allahverdiyeva et al., 2013; Shimakawa et al., 2015). Therefore, FLV is expected to contribute to P700 oxidation. The lack of FLV1/3 in S. 6803 causes PSI photoinhibition under artificial fluctuating light (Allahverdiyeva et al., 2013). However, under CO2 limitation (which suppresses photosynthetic CO2 fixation), deletions of FLV1/3 and FLV2/4 do not cause PSI photoinhibition in S. 6803 (Zhang et al., 2009) or Synechococcus elongatus PCC 7942 (S. 7942; Shaku et al., 2015), possibly because P700 stays oxidized under CO2 limitation regardless of the existence of FLV (Shaku et al., 2015). These data imply that FLV is not essential to keep P700 oxidized under CO2 limitation, at least in S. 6803 and S. 7942.

In this study, we found that the lack of FLV1/3 leads to growth inhibition under ambient [CO2] concentration ([CO2]) in the cyanobacterium Synechococcus sp. PCC 7002 (S. 7002), unlike S. 6803 and S. 7942 (Zhang et al., 2009; Shaku et al., 2015). The S. 7002 genome, like that of S. 7942, includes genes coding for FLV1/3 isozymes but not for FLV2/4 (Fujisawa et al., 2014). The genetic profiles of flu and other genes related to cyanobacterial AEF, including those of S. 7002, S. 6803, and S. 7942, are summarized in Table I. Shifting from CO2-saturated to CO2-limited conditions decreased total oxidizable P700 to approximately 10% in the flu knockout mutant of S. 7002 but not in those of S. 6803 or S. 7942. We demonstrated that the deletion of FLV in S. 7002 rendered it unable to oxidize P700, resulting in PSI photoinhibition. These findings show that there are different strategies in cyanobacteria to protect PSI against photooxidative damage under CO2 limitation.

RESULTS
Effects of FLV on the Growth of S. 7002 under Ambient [CO2]

We constructed the S. 7002 mutant, Δflu1/3, which lacks the flu and fco3 orthologs present in S. 6803 (SYNPCC7002_A1743 and SYNPCC7002_A1321; Supplemental Fig. S1). We found that the growth of S. 7002 Δflu1/3 is slower than that of the wild type under ambient [CO2] (Fig. 1). This response was not observed in either S. 6803 (Zhang et al., 2009) or S. 7942 (Shaku et al., 2015). Approximately 2 weeks after inoculation, the OD550 for Δflu1/3 was 70% lower than that for the wild type (Fig. 1A). The chlorophyll (Chl) content in the Δflu1/3 medium was half that of the wild type (Fig. 1B). These results indicate that S. 7002 requires FLV1/3 for optimal growth under ambient [CO2].

Effects of CO2 Limitation on Photosynthetic Parameters in Wild-Type and Δflu1/3 S. 7002

We hypothesized that PSI photoinhibition occurs under CO2 limitation in the absence of FLV-mediated AEF in S. 7002. We studied the effects of CO2 limitation on total oxidizable P700 and net photosynthetic oxygen evolution rates in S. 7002 wild type and Δflu1/3. After a 2-h exposure to CO2 limitation, neither PSI nor photosynthesis inactivation was detected in S. 7002 wild type (Fig. 2, A and B). Nevertheless, a significant posttreatment reduction in total oxidizable P700 (Fig. 2A) and suppression of photosynthesis (Fig. 2C) were observed in S. 7002 Δflu1/3. The dramatic decreases in photosynthetic parameters (0%–10% of pretreatment levels; Fig. 2, A and C) for Δflu1/3 indicate that the lack of FLV1/3 in S. 7002 causes severe PSI photoinhibition under CO2 limitation.

To determine whether the deletion of FLV-mediated AEF combined with CO2 limitation always causes PSI photoinhibition in cyanobacteria, we applied the same treatment to S. 6803 and S. 7942. For S. 6803, we used a

mutant deficient in the expression of all four flv genes (Δflv1/3/4), since the wild type of this species possesses FLV2/4 (Table I; Supplemental Fig. S1; Eisenhut et al., 2012). Unlike S. 7002, the amounts of total oxidizable P700 were the same before and after the treatment for both S. 6803 and S. 7942 even when the flv genes were not expressed (Supplemental Fig. S2, A and B). CO2 limitation also did not affect the dependence of photosynthetic oxygen evolution rates on photon flux density in either the wild type or the flv mutants of S. 6803 and S. 7942 (Supplemental Fig. S2, C–F). On the other hand, the deletion of FLV1/3 in S. 7942 decreased photosynthetic oxygen evolution rates even before CO2 limitation, particularly in high-light conditions (Supplemental Fig. S2, D and F), due to RISE (Shaku et al., 2015).

Effects of FLV on the Photosynthetic Parameters of PSII and PSI in S. 7002

To determine the relationship between PSI photodamage and P700 oxidation in S. 7002, we simultaneously monitored Chl fluorescence and the P700 redox state in PSI during the transition from CO2 saturation to CO2 limitation. We modified methods used in our previous

Figure 1. Growth of S. 7002 wild type and the mutant Δflv1/3 under ambient [CO2]. Optical density at 750 nm (OD750; A) and Chl (B) measurements were independently conducted three times, and the data are shown as means ± s.e. Black circles, S. 7002 wild type; red triangles, Δflv1/3. Differences between S. 7002 wild type and Δflv1/3 were analyzed by Student’s t test. Asterisks indicate statistically significant differences between S. 7002 wild type and Δflv1/3 at P < 0.05.

Figure 2. Reduced activities of PSI and photosynthesis in S. 7002 wild type (WT) and Δflv1/3 after 2-h exposures to CO2 limitation during illumination (290 μmol photons m−2 s−1). The reaction mixture contained fresh A+ medium and cyanobacterial cells (10 μg Chl mL−1). Residual total oxidizable P700 (A) and photosynthetic oxygen evolution rates (B and C) were measured before and after 1 h in the dark following treatments. Black and red symbols represent the wild type and Δflv1/3, respectively. Closed and open symbols represent the data before and after the treatments (B and C), respectively. Photosynthetic oxygen evolution rates were measured in the presence of 10 mM NaHCO3. Each measurement was conducted three times, and means ± s.e are shown. Differences between the data before and after the treatments were analyzed by Student’s t test. Asterisks indicate statistically significant differences at P < 0.05.
work (Shimakawa et al., 2015). Upon red actinic light (AL) illumination in S. 7002 wild type, incident quantum yields of PSI [Y(I)] and PSII [Y(II)] rose (by about 0.8 and 0.3, respectively). Thereafter, they began to decline (to about 0.6 and 0.1, respectively) due to a decrease in photosynthesis (Fig. 3A). CO₂ consumption suppressed photosynthesis. Y(I) and Y(II) were restored when CO₂ was added in the form of NaHCO₃ (Fig. 3A; Hayashi et al., 2014; Shimakawa et al., 2015). The P700 redox state also responded to CO₂ limitation. The suppression of photosynthetic linear electron flow increased the yield of oxidized P700 [Y(ND)]. This condition was alleviated by the addition of CO₂ (Fig. 3A). On the other hand, the yield of photoexcited P700 [Y(NA)] did not change in response to the shortage of CO₂ (Fig. 3A). Therefore, the PSI acceptor side limitation did not change after S. 7002 wild type was subjected to CO₂ limitation. It is unclear why Y(I) was significantly higher than Y(II) in this study. Cyclic electron flow around PSI may contribute to surplus Y(I) (see “Discussion”). The S. 6803 mutant ΔndhD1/2, which is deficient in the D subunits of NAD(P)H dehydrogenase, however, also had higher Y(I) than Y(II) (Supplemental Fig. S3). The large gap between Y(I) and Y(II) in cyanobacteria merits further investigation.

Next, we measured the photosynthetic parameters of PSII and PSI after the transition to CO₂ limitation in S. 7002 Δflv1/3. Before CO₂ deprivation, Y(I) and Y(II) in Δflv1/3 were lower (about 0.6 and 0.2, respectively) than those in the wild type, whereas Y(NA) was higher in the mutant (about 0.3) than in the wild type (about 0.1; Fig. 3). These results imply that FLV1/3 drives AEF in S. 7002, as it does for S. 6803 (Helman et al., 2003) and S. 7942 (Shaku et al., 2015). CO₂ limitation did not induce P700 oxidation in S. 7002 Δflv1/3 (Fig. 3B). An increase in Y(NA) indicated that the electron flux from P700 to the acceptor side of PSI was reduced further still (Fig. 3B). Y(I) also was considerably suppressed under CO₂ limitation (Fig. 3B). The addition of NaHCO₃ did not restore Y(I) or Y(II) (Fig. 3B). These results suggest that, unless FLV1/3-mediated AEF is active, PSI photo-inhibition occurs in S. 7002 during CO₂ limitation. For S. 7002, FLV1/3 plays a primary role in oxidizing the PET system under CO₂ limitation. Recently, we found that S. 7002 drives an oxygen-dependent AEF to restore linear electron transport during CO₂-limited photosynthesis. This process is particularly evident in cells grown under ambient [CO₂] (Shimakawa et al., 2016). In this study, a simultaneous measurement of oxygen concentration and Chl fluorescence was performed in S. 7002 Δflv1/3 grown under ambient [CO₂] (Supplemental Fig. S4), indicating that FLV1/3 is the molecular mechanism of the oxygen-dependent AEF we found in S. 7002 (Shimakawa et al., 2016).

Effects of FLV on the Photosynthetic Parameters of PSII and PSI in S. 6803 and S. 7942

The photosynthetic parameters of PSII and PSI responded differently to CO₂ limitation in S. 6803 than they did in S. 7002. In S. 6803 wild type, Y(I) and Y(II) decreased to minimum values and then started to recover, reaching approximately 90% and 60% of the initial values, respectively, without the addition of NaHCO₃ (Supplemental Fig. S5A). This recovery occurred due to the activation of an oxygen-dependent AEF driven by FLV1/4 but not by FLV1/3 (Shimakawa et al., 2015; Supplemental Figs. S5 and S6). The AEF stimulated linear electron flow, which decreased both Y(ND) and Y(NA) (Supplemental Fig. S5A). In S. 6803, the deletion of FLV1/3 reduced both Y(I) and Y(II) relative to the wild type before CO₂ consumption (Supplemental Fig. S5B). For S. 6803 Δflv1/3 before CO₂ depletion, Y(ND) was lower than that of the S. 6803 wild type, whereas Y(NA) in the mutant was higher than that of the wild type (Supplemental Fig. S5B). These findings concur with those of previous studies showing that FLV1/3-mediated AEF can oxidize P700 (Helman et al., 2003; Allahverdiyeva et al., 2013; Hayashi et al., 2014). The suppression of photosynthetic linear electron flow caused by CO₂ limitation induced P700 oxidation in S. 6803 even in the absence of...
FLV-mediated electron flow (Supplemental Fig. S5D). The oxidized P700 was reduced by the activation of FLV2/4-mediated AEF or by the resumption of photosynthetic CO₂ fixation (Supplemental Fig. S5).

S. 7942 wild type lacks FLV2/4-mediated AEF (Hayashi et al., 2014), so its PSII and PSI photosynthetic parameters responded to CO₂ limitation in almost the same manner as did those of S. 6803 Δflv4. For the S. 7942 wild type, both Y(I) and Y(II) decreased and remained low under CO₂ limitation, but they were restored by adding NaHCO₃ (Supplemental Fig. S7A). The increase in Y(ND) reflected P700 oxidation in response to CO₂ limitation and was observed in both the wild type and Δflv1/3 of S. 7942 (Supplemental Fig. S7). The mutant of S. 7942 also had a higher Y(ND) than did the S. 7942 wild type under CO₂ limitation (Supplemental Fig. S7B). These results align with the findings of a previous study (Shaku et al., 2015).

**DISCUSSION**

Table II summarizes the findings of previous studies and this study and shows two main conclusions: (1) P700 oxidation is linked directly to the protection of PSI against photoinhibition; and (2) in cyanobacteria, there are several strategies, including FLV, to alleviate PSI photoinhibition. In S. 7002, FLV1/3 mediates oxygen-dependent AEF that regulates the PSI redox state and promotes P700 oxidation under CO₂ limitation (Fig. 3; Supplemental Figs. S4; Shimakawa et al., 2016). In S. 7002, the lack of FLV-mediated AEF resulted in P700 reduction, photosynthesis suppression, PSI photoinhibition, and growth retardation (Figs. 1 and 2). These observations correspond to higher transcript levels of flv1/3 under CO₂ limitation (Ludwig and Bryant, 2012). In contrast, S. 6803 and S. 7942 keep P700 oxidized under CO₂ limitation independently of FLV-mediated AEF (which protects PSI against photooxidative damage; Supplemental Figs. S2, S5, and S7; Zhang et al., 2009; Shaku et al., 2015). In cyanobacteria, FLV has diverse physiological significance as the agent for oxygen-dependent AEF.

In this study, we showed that P700 oxidation protects PSI against photoinhibition in cyanobacteria (which are the progenitors of oxygenic phototrophs). Photooxidative damage in PSI is caused by ROS generated by excitation energy transfer from P700 ultimately to oxygen. Therefore, photooxidizable P700 in PSI can produce ROS, whereas oxidized P700 cannot be excited by photon energy. PSI photoinhibition is caused by O₂⁻ produced on the acceptor side of PSI when NADP⁺ regeneration is limited (Hihara and Sonoike, 2001). Added hydrogen peroxide reacts with reduced iron in iron-sulfur centers to form hydroxyl radicals that destroy PSI instantaneously (Hihara and Sonoike, 2001; Sonoike, 2011). P700 oxidation is expected to negate the effect of hydroxyl radicals by suppressing O₂⁻ generation and by oxidizing the iron-sulfur centers (Sonoike 1996). Recently, it was suggested that ¹O₂ triggers PSI photoinhibition (Cazzaniga et al., 2012, 2016; Takagi et al., 2016). Keeping P700 oxidized should help suppress ¹O₂ generation. P700 oxidation alleviates PSI photoinhibition in sunflower (Helianthus annuus) leaves during repetitive short saturated-pulse treatment (Sejima et al., 2014). There may be a mechanism common both to plants and cyanobacteria for protecting PSI from photooxidative damage. P700 oxidation would be a hedge against ROS generation.

In S. 6803 and S. 7942, P700 remained oxidized under CO₂ limitation even without FLV1/3 and FLV2/4 (Supplemental Figs. S5 and S7). There is, therefore, a P700 oxidation mechanism that operates independently of FLV-mediated AEF under CO₂ limitation. One candidate is cyclic electron flow around PSI, which helps induce the proton gradient across the thylakoid membrane (Miyake et al., 2004, 2005). Acidification of the luminal side reduces the oxidation activity of plastoquinol in the Cyt b₅f/f complex and limits the electron flux from plastoquinol to P700 through plastocyanin (or Cyt c). These hypotheses are supported by the fact that Y(I) is greater than Y(II) for all cyanobacterial strains tested except for S. 7002 Δflv1/3 (Fig. 3; Supplemental Figs. S5 and S7). Nevertheless, we also found that Y(I) is greater than Y(II) for both S. 6803 wild type and its mutant Δndl1/2 (Supplemental Fig. S3). Therefore, reduced activity of NAD(P)H dehydrogenase-mediated cyclic electron flow (Ohkawa et al., 2000) is not linked to the ratio of Y(I) to Y(II). Moreover, cyclic electron transport rates in S. 6803 and S. 7002 are negligible relative to their photosynthetic linear and

respiratory electron transport rates (Yu et al., 1993; Shimakawa et al., 2014). We could not determine why Y(I) differed from Y(II) in cyanobacteria. The contribution of phycobiliprotein to minimum fluorescence yield may account for it (Campbell et al., 1998), as might the difference between the quality of the growth light and that of the light-emitting diode (LED)-sourced AL used in the experiments. Another candidate for the P700 oxidation mechanism is the suppression of the Q cycle when plastquinone is reduced. In this case, the electron flux from the Cyt b 6/f complex to P700 in PSI decreases. This response is called RISE (Shaku et al., 2015), and it may be the main driver of P700 oxidation under CO 2 limitation in cyanobacteria. Respiratory terminal oxidases like Cyt c oxidase and cytochrome b d-type quinol oxidase also may contribute to the oxidation of the donor side of PSI under CO 2 limitation (Beardall et al., 2003; Trouillard et al., 2012; Lea-Smith et al., 2013). It is difficult, however, to explain why Y(II) decreased during CO 2 limitation in the cyanobacteria we studied (Fig. 3; Supplemental Figs. S5 and S7).

In S. 6803, FLV2/4 may receive electrons from the acceptor side of PSI. In both S. 6803 wild type and its mutant Δflv1/3, the increases in Y(I) and Y(II) indicate that PSI electron flux is restored under CO 2 limitation (Supplemental Fig. S5; A and B). Unlike S. 6803 wild type and Δflv1/3, neither Δflv4 nor Δflv1/3/4 experienced an increase in Y(I) (Supplemental Fig. S5; C and D). Removing oxygen lowered Y(I) under CO 2 limitation in S. 6803 wild type but not in Δflv4 (Supplemental Fig. S6). These data suggest that FLV2/4 mediates an oxygen-dependent AEF on the acceptor side of PSI (Hayashi et al., 2014; Shimakawa et al., 2015), as does FLV1/3 (Helman et al., 2003), since both FLV sets have similar primary structures (Fujisawa et al., 2014) and enzymatic characteristics of recombinant proteins (Vicente et al., 2002; Shimakawa et al., 2015). However, we cannot exclude the possibility that the relief of excitation pressure at PSI by FLV2/4 (Bersanini et al., 2014) provides an enhancement of Y(I) during CO 2-limited photosynthesis in S. 6803. FLV2/4 is known to interact with PSII and phycobilisomes (Bersanini et al., 2014), so in S. 6803, it may have multiple functions to alleviate photoinhibition under low CO 2.

### MATERIALS AND METHODS

#### Growth Conditions and Chl a Determination

Cyanobacterial cultures were maintained under continuous fluorescent lighting (25°C, 50 μmol photons m -2 s -1) on BG-11 solid medium (for Synechocystis sp. PCC 6803 and Synechococcus elongatus PCC 7942) and A 1 solid medium (for Synechococcus sp. PCC 7002; Allen, 1968; Stevens and Porter, 1980). Cells from both cultures were inoculated into liquid medium (initial OD 750 = 0.1–0.2) and grown on a rotary shaker (100 rpm) under continuous fluorescent lighting (25°C, 150 μmol photons m -2 s -1) at 2,000 μL L -1 [CO 2]. OD 750 values were measured with a spectrophotometer (U-2800A; Hitachi). For all photosynthetic parameter measurements, cells from the exponential growth phase were used. In the experiments for Figure 1 and Supplemental Figure S4, S. 7002 was grown under ambient [CO 2].

For Chl measurements, cells from 0.1- to 1-mL cultures were centrifugally harvested and resuspended by vortexing in 1 mL of 100% (v/v) methanol. After incubation at room temperature for 5 min, the suspension was centrifuged at 10,000g for 5 min. Total Chl a was spectrophotometrically determined from the supernatant (Grimme and Boardman, 1972).

#### Bioinformatics

All the S. 7002, S. 6803, and S. 7942 gene sequence data used in this study were obtained from Cyanobase (http://genome.microbeds.jp/Cyanobase; Fujisawa et al., 2014). For the flv1–4, cox, cyd, ars, ndhD1/2, and pgr5 gene sequences, BLAST searches were conducted in Cyanobase.

#### Statistical Analysis

Student’s t-tests were applied to detect differences. All statistical analyses were performed using Microsoft Excel 2010 (Microsoft) and JMP8 (SAS Institute).

#### Generation of Mutants

The triple mutant of S. 6803 deficient in flv1 (Δflv1/3), flv3 (Δflv3/5/0), and flv4 (Δflv0/2) was generated by transforming Δflv1/3 (Hayashi et al., 2014) using the flv4 construct (Shimakawa et al., 2013). PCR was used to confirm the complete segregation of flv1 and flv4 (Supplemental Fig. S1A). The disruption of FLV3 proteins was verified by immunoblotting with a specific antibody to FLV3 (see “Immunoblot Analysis” below), since a nonspecific band was observed near the target band in the PCR analysis (Supplemental Fig. S1B).

To construct the double mutant of S. 7002 lacking flv1 (SYNPCC7002_A1743) and flv3 (SYNPCC7002_A1321) orthologs, PCR was used to amplify each genomic region encoding A1743 and A1321 with the up f and dn r primer sets (Supplemental Table S1). They were then cloned into the pGEM-T Easy vector (Promega). The recombinant plasmids containing A1743 and A1321 were linearized and amplified by inverse PCR with the up f and dn r primer sets (Supplemental Table S1). They were then applied to the In-Fusion reaction (Takara) using chloramphenicol and kanamycin resistance genes (Cm’ and Kan’) derived from pACYC184 and pUC4K vectors, respectively (Rose, 1988; Taylor and Rose, 1988). Transformation of S. 7002 was performed by the standard procedure (Frigaard et al., 2004). Single mutants (Δflv1/3 and Δflv3/0) were selected on 0.5% BG-11 agar plates containing chloramphenicol (15 μg mL -1) or kanamycin (50 μg mL -1). The double mutant (Δflv1/3) was generated by transforming Δflv1/3 with the flv3/0 construct. The mutants were selected on plates containing both chloramphenicol (15 μg mL -1) and kanamycin (50 μg mL -1). Complete segregation was confirmed by PCR (Supplemental Fig. S2C).

#### Immunoblot Analysis

S. 6803 wild-type and Δflv1/3/4 cell cultures (10 mL) were harvested by centrifugation and pellet resuspension in 500 mL of extraction buffer (50 mM HEPES-KOH [pH 7.5], 1 mM MgCl 2, 2 mM EDTA, and 1 mM phenylmethylsulfonyl fluoride). The suspensions were homogenized with glass beads using Bug Crusher GM-01 (Taitec) and centrifuged at 13,000g for 30 min at 4°C. The supernatants were treated as extracted soluble fractions. Protein concentrations in them were determined with the Pierce 660 nm Protein Assay (Thermo Scientific) using bovine serum albumin as the standard. Soluble fractions containing 5 μg of protein were analyzed by SDS-PAGE. After electrophoresis, the proteins were electrotransferred to a polyvinylidene fluoride membrane and detected by an FLV3-specific antibody (kindly provided by Dr. H. Yamamoto).

#### Measurement of Chl Fluorescence and P700

Chl fluorescence and P700 were measured simultaneously with the Dual-PAM-100 system (Heinz Walz) at room temperature (25°C ± 2°C). For S. 6803 and S. 7942, the reaction mixtures (2 mL) contained 50 mM HEPES (pH 7.5) and the cells (10 μg Chl mL -1). For S. 7002, the reaction mixture consisted of fresh A 1 medium and the cells (10 μg Chl mL -1). During the measurements, the reaction mixtures were stirred with a magnetic micro stirrer. The photon flux densities of red AL (LED with peak emission at 635 nm) are shown in the corresponding figure legends. Y(II) reflects the apparent electron flux in photosynthetic linear electron transport (Genty et al., 1989). It was calculated from Chl fluorescence as 
\[
F_{\text{m}} - F_n/F_{\text{m}}' (\text{where } F_{\text{m}}' = \text{maximum variable fluorescence yield, } F_n = \text{steady-state fluorescence yield, and } F_{\text{m}} = \text{minimum fluorescence yield; Schreiber et al., 1972})
\]
1986; van Kooten and Snel, 1990). The reduct state of P700 was determined according to the method of Klughammer and Schreiber (1994, 2008). In this procedure, \( P_{m} \) was the maximum P700 photooxidation level obtained by saturated pulse light under far-red illumination, \( P = \) the oxygen level of P700 under AL, \( P_{m} = \) maximum oxidation level of P700 obtained by saturation pulse under AL illumination, \( Y(P) = \frac{P_{m} - P}{P_{m}} \) is the incident quantum yield of photoreduction conversion, \( Y(\Delta N) = \frac{\Delta N}{P_{m}} \) is the quantum yield of nonphotochemical energy dissipation due to donor-side limitation, and \( Y(\Delta N) = \frac{P_{m} - P_{m}'}{P_{m}} \) is the quantum yield of nonphotochemical energy dissipation due to acceptor-side limitation. The sum of the three factors \( Y(I) + Y(\Delta N) + Y(\Delta N) \) = 1. For the simultaneous measurements of \( Y(I) \), \( Y(\Delta N) \), and \( Y(\Delta N) \), a 300-ms saturation pulse (10,000 amol photons m \(^{-2} \) s \(^{-1} \)) was supplied every 10 min. The stirrer was turned off 5 s before the saturation pulse was applied.

**Measurement of Oxygen Exchange**

Oxygen uptake and evolution were measured with a Clark-type oxygen electrode (Hansatech; Shimakawa et al., 2015). For S. 6803 and S. 7942, the re-array mixture (2 mL) contained 50 mM HEPES (pH 7.5), 10 mM NaHCO\(_3\) and the cells (10 \( \mu \)g Chl mL \(^{-1} \)). For S. 7002, the mixture (2 mL) contained fresh A medium, 10 mM NaHCO\(_3\) and the cells (10 \( \mu \)g Chl mL \(^{-1} \)). Cells were illuminated with AL (red light, 620 < wavelength < 695 nm; photon flux densities are indicated in the figure legends) at 25°C. During the measurements, the reaction mixture was stirred with a magnetic micro stirrer.

Oxygen concentration and Chl fluorescence were measured simultaneously (Supplemental Fig. S4). The relative fluorescence of Chl a was measured with a Chl fluorometer (PAM-101; Heinz Walz; Schreiber et al., 1986; Shimakawa et al., 2015). Pulse-modulated excitation was achieved using an LED lamp with peak emission at 650 nm. Modulated fluorescence was measured at A > 710 nm using a Schott KG9 long-pass filter. The fluorescence terminology follows van Kooten and Snel (1990).

**Supplemental Data**

The following supplemental materials are available.

**Supplemental Figure S1.** Insertional inactivation of \( flg \) genes in S. 6803 and S. 7002.

**Supplemental Figure S2.** Decreased activities of PSI and photosynthesis in the wild type and the \( flg \) mutants of S. 6803 and S. 7942 after 2-h exposure to \( \text{CO}_2 \) limitation during illumination.

**Supplemental Figure S3.** Responses of the photosynthetic parameters of PSI and PSII to \( \text{CO}_2 \) limitation in the mutant of S. 6803 defective in \( ndhD1 \) and \( ndhD2 \).

**Supplemental Figure S4.** Photosynthetic parameters of S. 7002 wild type and \( \Delta \Phi\text{t1/3} \) grown in ambient [\( \text{CO}_2 \)].

**Supplemental Figure S5.** Responses of the photosynthetic parameters of PSII and PSI to \( \text{CO}_2 \) limitation in S. 6803 wild type and the mutants \( \Delta \Phi\text{t1/3} \), \( \Delta \Phi\text{t4/3} \), and \( \Delta \Phi\text{t0/3/4} \).

**Supplemental Figure S6.** Effects of eliminating oxygen on the photosynthetic parameters of PSI and PSII under \( \text{CO}_2 \) limitation in S. 6803 wild type and the mutant \( \Delta \Phi\text{t1/3} \).

**Supplemental Figure S7.** Responses of the photosynthetic parameters of PSI and PSII to \( \text{CO}_2 \) limitation in S. 7942 wild type and the mutant \( \Delta \Phi\text{t1/3} \).

**Supplemental Table S1.** Primers used in this study.

**ACKNOWLEDGMENTS**

We thank Akihiko Kondo, Tomohisa Hasunuma, and Dr. Shimepi Aikawa (Kobe University) for supplying the S. 7002 wild type; Dr. Hiroshi Ohkawa (Hirosaki University) and Kintake Sonoike (Waseda University) for giving us the mutant \( \Delta \text{ndhD1/2} \); Dr. Hiroshi Yamamoto (Kyoto University) for the gift of the anti-FLV3 antibody; and Editage (www.editage.jp) for English language editing.

Shimakawa et al.

Fig. S1. Insertional inactivation of *flv* genes in S. 6803 and S. 7002. (A) DNA fragments amplified by PCR showing complete segregation of the inactivated genes, *flv1* (*sll1521*) and *flv4* (*sll0217*). WT, S. 6803 WT; Δt, the triple mutant of S. 6803 (Δ*flv1/3/4*). (B) Western blot analysis showing the lack of the *flv3* (*sll0550*) gene product. Extracted soluble fractions (5 µg protein/lane) of S. 6803 WT and Δ*flv1/3/4* were analyzed. (C) DNA fragments amplified by PCR showing complete segregation of the inactivated genes, *flv1* (*SYNPCC7002_A1743*) and *flv3* (*SYNPCC7002_A1321*). WT, S. 7002 WT; Δs, single mutants of S. 7002 (Δ*flv1* and Δ*flv3*); Δd, the double mutant of S. 7002 (Δ*flv1/3*).
Fig. S2. Decreased activities of PSI and photosynthesis in the WT and the flv mutants of S. 6803 (A, C, E) and S. 7942 (B, D, F) after 2-hour exposures to CO₂ limitation during illumination (290 µmol photons m⁻² s⁻¹). Reaction mixtures contained 50 mM HEPES (pH 7.5) and cells (10 µg Chl mL⁻¹). Residual total oxidizable P700 (A, B) and photosynthetic O₂--evolution rates (C–F) were measured before and after 1 h in the dark following treatments. Black and red symbols represent each WT and flv mutant, respectively. Closed and open symbols represent the data before and after the treatments (C–F), respectively. Photosynthetic O₂-evolution rates were measured in the presence of 10 mM NaHCO₃. Each measurement was conducted three times, and the means ± SD are shown.
Fig. S3. Responses of the photosynthetic parameters of PSII and PSI to CO₂ limitation in the mutant of S. 6803 deficient in ndhD1 and 2 (ΔndhD1/2). Reaction mixtures contained the cells (10 µg Chl mL⁻¹). (A) Time courses of the parameters of PSII and PSI. Y(I), black circles; Y(ND), red triangles; Y(NA), blue squares; Y(II), white diamonds. Red AL (180 µmol photons m⁻² s⁻¹) was activated at time zero. NaHCO₃ (10 mM) was added as indicated. Measurements were conducted three times, and representative data are shown. (B) The relationship between Y(II) and Y(I) throughout the measurement in S. 6803 WT (Black circles) and ΔndhD1/2 (green stars). Data plotted are obtained from Figs. 3A and S2A, respectively.
Fig. S4. Photosynthetic parameters of S. 7002 WT and Δflv1/3 grown in ambient [CO₂]. (A, B) Time courses of dissolved O₂ concentration (red lines) and relative Chl fluorescence yield (black lines) in S. 7002 WT (A) and Δflv1/3 (B). Experimental procedures were similar to those in our recent study (Shimakawa et al., 2016). Cells (10 μg Chl mL⁻¹) were illuminated with measuring light (ML) as indicated. Red AL (300 μmol photons m⁻² s⁻¹, 620 < λ < 695 nm) was activated at time zero. Dashed arrows indicate changes in the position of the Chl fluorescence signal. Chl fluorescence parameters are: F₀, minimum fluorescence under ML; Fₛ, steady-state fluorescence under AL; Fₘ', maximum variable fluorescence under saturating light. NaHCO₃ (10 mM) was added as indicated. Experiments were performed three times, and representative data are shown. (C) Time courses of Y(II) shown as mean ± SD (n = 3). Black circles, S. 7002 WT; red triangles, Δflv1/3. (D) Relationships between gross O₂ evolution rates and Y(II) in S. 7002 WT (black circles) and Δflv1/3 (red triangles). Photosynthetic O₂ evolution rates were determined at both CO₂-saturated and CO₂-limited conditions in separate experiments (n = 3) following the methods described in Shimakawa et al. (2016).
Fig. S5. Responses of the photosynthetic parameters of PSII and PSI to CO₂ limitation in S. 6803 WT (A) and the mutants Δflv1/3 (B), Δflv4 (C) and Δflv1/3/4 (D). Reaction mixtures contained the cells (10 µg Chl mL⁻¹). Y(I), black circles; Y(ND), red triangles; Y(NA), blue squares; Y(II), white diamonds. Red AL (180 µmol photons m⁻² s⁻¹) was activated at time zero. NaHCO₃ (10 mM) was added as indicated. Measurements were conducted three times and representative data are shown.
Fig. S6. Effects of eliminating O$_2$ on the photosynthetic parameters of PSII and PSI under CO$_2$ limitation in S. 6803 WT (A) and the mutant Δflv4 (B). Reaction mixtures contained the cells (10 µg Chl mL$^{-1}$). Y(I), black circles; Y(ND), red triangles; Y(NA), blue squares; Y(II), white diamonds. Red AL (180 µmol photons m$^{-2}$ s$^{-1}$) was activated at time zero. Glucose (5 mM), catalase (250 units mL$^{-1}$), and glucose oxidase (GlcOX, 5 units mL$^{-1}$) were added as indicated. Measurements were conducted three times and representative data are shown.
Fig. S7. Responses of the photosynthetic parameters of PSII and PSI to CO$_2$ limitation in S. 7942 WT (A) and the mutant $\Delta$flv1/3 (B). Reaction mixtures contained the cells (10 µg Chl mL$^{-1}$). Y(I), black circles; Y(ND), red triangles; Y(NA), blue squares; Y(II), white diamonds. Red AL (180 µmol photons m$^{-2}$ s$^{-1}$) was activated at time zero. NaHCO$_3$ (10 mM) was added as indicated. Measurements were conducted three times and representative data are shown.
